Distributed Consensus

No Faults

Problem Description

Assumptions:

- $n$ processes connected by a full graph.
- Each process starts with an initial value $\{0, 1\}$.
- **Synchronous settings:** every message is received (if not lost) in the same epoch in which it is sent.
- **No Faults case:** No process faults or message omissions.
- solution is required within $r$ rounds for some fixed $r$. 
No Faults

Problem Description (cont.)

Requirements:

• **Agreement**: All processes decide on the same value.

• **Validity**: If a process decides on a value, there was a process that started with that value.

What if we eliminate the validity requirement?

The validity requirement eliminates trivial meaningless solutions.
No Faults
One-Round Algorithm

- Send your value to all the processes.
- If all the values you have (including your own) are 1 then decide 1. Otherwise decide 0.

Message Omissions
Problem Description

Assumptions:
- \( n \) processes connected by a full graph.
- Each process starts with an initial value \( \{0, 1\} \).
- Synchronous setting - solution is required within \( r \) rounds for some fixed \( r \).
- Any number of messages may be lost.
Message Omissions
Problem Description (cont.)

Requirements:

• **Agreement:** All processes decide on the same value.

• **Validity:** If all processes start with 0, then the decision value is 0; if all processes start with 1 and no message is lost, then the decision value is 1.

Notice that the validity requirement is **weaker** than the original validity requirement.

---

Message Omissions
Consensus is Not Solvable!

**Theorem:** There is no algorithm that solves the consensus problem for even 2 processes.

**Definition:** Execution $\alpha$ is **indistinguishable** from execution $\beta$ with respect to process $p$ if in both $\alpha$ and $\beta$, $p$ has the same initial state and receives exactly the same messages at the same rounds.

$$\alpha^p \sim^p \beta$$
Proof

\(\alpha_1\): Both processes start with 1 and no message is lost.

\(\alpha_2\): Similar to \(\alpha_1\) except that the last message from \(p\) to \(q\) is lost.

\(\alpha_3\): Similar to \(\alpha_2\) except that the last message from \(q\) to \(p\) is lost.

\(\alpha_1 \sim^p \alpha_2\) \quad \(\alpha_2 \sim^q \alpha_3\)

Proof (cont.)

\(\alpha_x\): Both processes start with 1 and all messages are lost.

\(\beta_x\): Similar to \(\alpha_x\) except that \(q\) starts with 0.

\(\beta_y\): Similar to \(\beta_x\) except that \(p\) starts with 0.

\(\alpha_x \sim^p \beta_x\) \quad \(\beta_x \sim^q \beta_y\)

Contradiction
Message Omissions
Randomized Consensus

An Adversary is an arbitrary choice of:

- Initial values for all processes.
- Subset of \( \{(p_1, p_2, i)\} \) where \( p_1, p_2 \) are processes and \( i \) is a round number.

The subset represents which messages are lost.

Message Omissions
Randomized Solution

Requirements:

- **Agreement:** For any adversary \( A \):
  
  The probability that some process decides 0 and some process decides 1 is less or equal to \( \varepsilon \).

- **Validity:** If all processes start with 0, then the decision value is 0; if all processes start with 1 and no message is lost, then the decision value is 1.
Message Omissions
A Randomized Algorithm

At initialization one specific process, $p$, chooses a key at random, uniformly from the range [1..$r$].

At each round the processes send the following:

- Initial value.
- Key (for process $p$ only).
- Color

Each process holds a variable color initialized to green. If a red message was received, or a message was missed, the process sets color to red.

Message Omissions
A Randomized Algorithm (cont.)

Decision Rule:

A process decides 1 after $r$ rounds if it knows that at least one process started with 1, it knows the value of key, and it has received all the messages in all the first key rounds and all of them were green. Otherwise, it decides 0.
Correctness Proof

Set $r$ to be an integer that is bigger or equal to the desired $1/\varepsilon$. The algorithm satisfies the agreement and validity requirements because for any adversary:

- If no message is lost then all processes get all messages and decisions will be identical.
- Look at the first message omitted by the adversary: only if this message is omitted at round $key$ there might be disagreement.
- Remember that $key$ is selected uniformly at random from the range $[1..r]$.

Fail-Stop Faults

Problem Description

Assumptions:

- $n$ processes connected by a full graph.
- Each process starts with an initial value $\{0, 1\}$.
- Synchronous setting - solution is required within $r$ rounds for some fixed $r$.
- The number of Fail-Stop faults is bounded in advance to $f$. A process may fail in the middle of message sending at some round. Once a process fails, it never recovers.
- No omission failures.
Fail-Stop Faults
Problem Description (cont.)

Requirements:

- **Agreement:** All correct processes do decide on the same value.
- **Validity:** If a correct process decides on a value, there was a process that started with that value.

Fail-Stop Faults

\( f+1 \) Rounds Algorithm

Each process maintains a vector containing a value for each process \( \{0,1,u\} \). \( u = \) undefined.

\[
\text{round}\{\hspace{1cm}
\begin{align*}
\bullet & \text{ Send your vector to all processes.} \\
\bullet & \text{ Update local vector according to the received vectors (in case local vector has a “}\ u\text{”, and any of received vectors contain “0” or “1’).} \\
\bullet & \text{ After } f+1 \text{ rounds decide according to the local vector. If you have 1 in the vector then decide 1, otherwise decide 0.}
\end{align*}
\]
\]
